## ABSTRACT

Subduction initiation and sequent evolution of oceanic lithosphere at convergent plate boundaries have important implications for our understanding of plate tectonics. Using zircon U-Pb and Lu-Hf isotopic and whole-rock geochemical data of newly identified Baijianshan diorites and Dawanbei and Dabanxi rhyolites from the center of the North Altun Orogenic Belt, we provide the time constraint for the initial subduction of the Proto-Tethys Ocean lithosphere and back-arc extension in the northern Altun Mountains. Zircon U-Pb ages show that the Baijianshan diorites emplaced at ~535 Ma and the Dawanbei and Dabanxi rhyolites erupted at ~495 Ma. The Baijianshan diorites share most features of high-K calc-alkaline high-Mg andesites, characterized by moderate SiO<sub>2</sub> contents (56.34–57.65 wt.%), high MgO contents (4.72–5.26 wt.%) and Mg<sup>#</sup> (57–65) values, and LREE and LILE enrichment relative to HREE and HFSE (Nb/La = 0.46–0.78). Their elemental geochemistry and coupled negative whole-rock  $\epsilon_{\text{Nd}}(t)$  (-9.1 to -8.5) and zircon  $\epsilon_{\text{Hf}}(t)$  (-15.4 to -10.9) values suggest that the diorites were formed by interaction between the subducted sediment-derived melts and peridotites in the mantle wedge. The Dawanbei and Dabanxi rhyolites are metaluminous to weakly peraluminous, and have high SiO<sub>2</sub> (70.07–78.65 wt.%) and Na<sub>2</sub>O (2.27–5.97 wt.%) contents, and low K<sub>2</sub>O (0.95–4.72 wt.%) contents. The rhyolites are enriched in most incompatible trace elements (e.g. Rb, Th, Zr, Hf and REE), and show affinity with A<sub>2</sub>-type granites. Isotopically, they have whole-rock  $\epsilon_{\text{Nd}}(t)$  values of -0.7 to -0.2 and zircon  $\epsilon_{\text{Hf}}(t)$  values of -2.3 to 6.4. Geochemical and isotopic compositions suggest that these rhyolites were derived through shallow (1–3 kbar) dehydration melting of basaltic rocks. Our analysis together with the regional geology of the northern Altun Mountains indicates that subduction of the Proto-Tethys Ocean lithosphere began started at ~535 Ma in the northern Altun Mountains. The juvenile A-type rhyolites (~495 Ma) are spatially and temporally associated with the Dawan high-Mg andesites and diorites (480–495 Ma), indicating that they were likely formed in a back-arc basin that was extending due to rollback of subducted oceanic lithosphere. The subduction process most likely continued until ~460 Ma and the Proto-Tethys Ocean finally closed at ~440 Ma. As a result, the central Altun terrane, as well as Tianshuihai-Mazar, Central Qilian, and North Qinling docked to the northern margin of Eastern Gondwana at ~440 Ma.

## 1. Introduction

Subduction initiation and back-arc extension are important tectonic processes, and are generally associated with negative buoyancy of oceanic lithosphere (Cramer et al., 2020; Stern and Gerya, 2018; Tontini et al., 2019) and trench retreat (Gueydan et al., 2017; Magni et al.,

2017), respectively. The timing of subduction initiation and identification of arc and back-arc systems can therefore provide critical information for paleo-subduction zone development (e.g. Chen et al., 2014; Keenan et al., 2016; Song et al., 2013; Xia et al., 2012). In addition, subduction initiation can induce partial melting of the oceanic slab and overlying sediments, leading to the formation of adakitic rocks and high-Mg andesites (Defant and Drummond, 1990; Peacock, 1990). Asthenospheric upwelling caused by slab rollback can produce a wide variety of magmatic rocks (e.g. adakites, mafic dykes and high-Mg andesites), and may also cause a back-arc extension, resulting in the

generation of back-arc basin basalts (BABB) and A-type granitoids (Ewart et al., 1998; Shinjo et al., 1999; Sibuet et al., 1987).

The Proto-Tethys Ocean opened during the late Neoproterozoic due to the breakup of Rodinia and mainly closed at the end of the early Silurian (Li et al., 2018a; Matte et al., 1996). A better understanding of the evolution of the Proto-Tethys Ocean is important for reconstructing the East Asia continents in Proto-Tethys realm. Based on the age of ophiolite complex and rift-related volcanism, recent studies indicated that the Proto-Tethys Ocean in Qingling-Qilian-Kunlun was developed in the Late Neoproterozoic (~600–580 Ma) (Dong et al., 2011; Song et al., 2013; Xu et al., 2015), subducted at ~520 Ma (Chen et al., 2014; Liu et al., 2016a; Meng et al., 2017; Song et al., 2013; Xia et al., 2012) and closed at ~440–430 Ma (Song et al., 2014, 2018; Yang et al., 2018; Zhang et al., 2013).

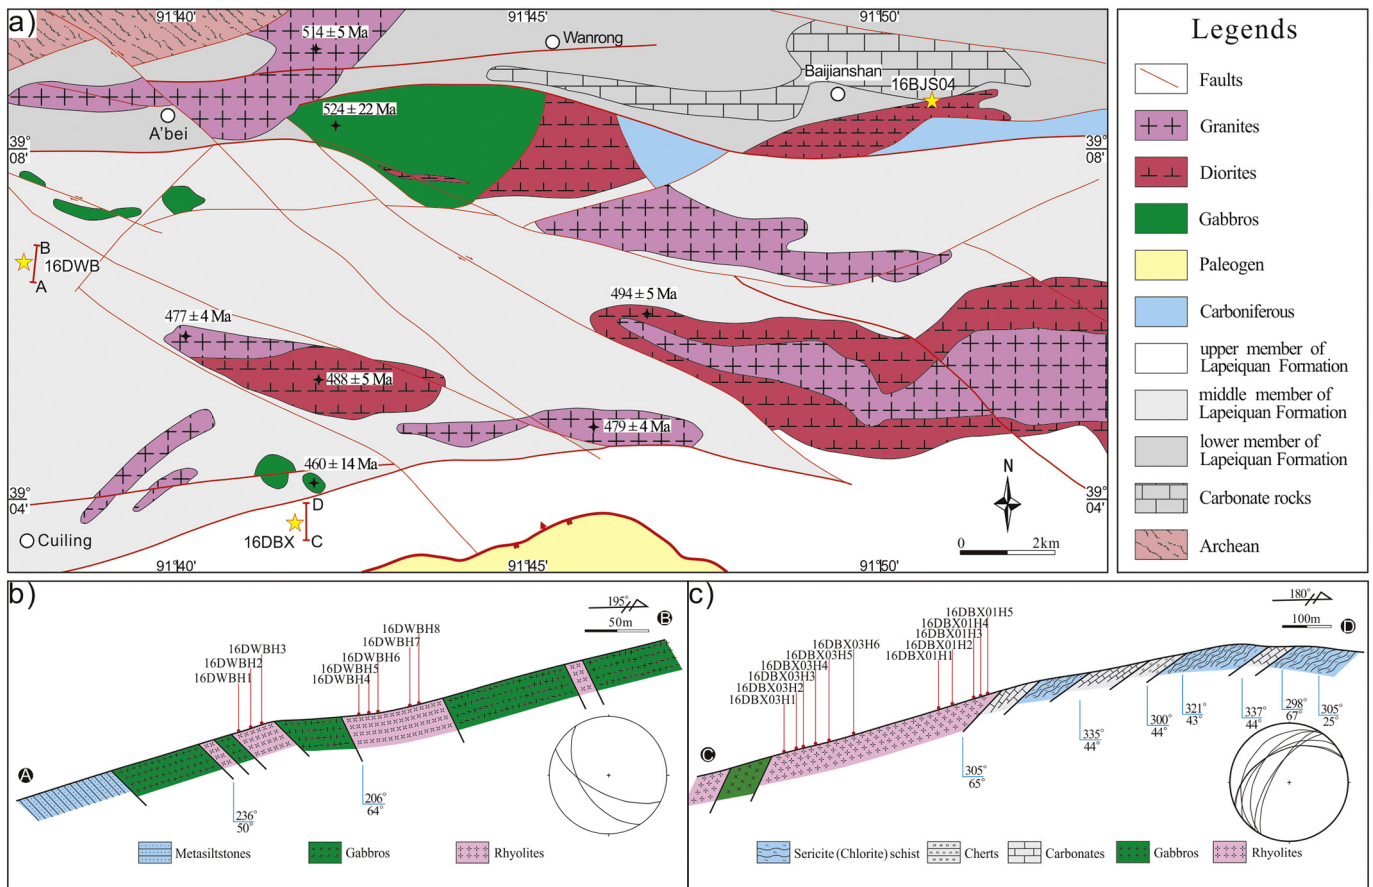

The North Altun Orogenic Belt (NAOB) is one of the key tectonic units of the Altun Orogen which is an important segment of the Qingling-Qilian-Kunlun orogenic system. As the northernmost orogenic collage of the Proto-Tethys domain, the NAOB is a well-preserved early Paleozoic trench–arc–basin system (Zhang et al., 2017) that is critical for the understanding of the Proto-Tethys Ocean evolution (Li et al., 2018a). Although the tectonic evolution of the NAOB is divided into three stages and it is known that subduction of oceanic slab occurred during 520–460 Ma (Han et al., 2012; Liu et al., 2016b; Meng et al., 2017; Wu et al., 2009; Ye et al., 2018; Zheng et al., 2019), the subduction history remains enigmatic. In particular, the timing of initial subduction and back-arc extension in NAOB is poorly constrained.

Here we present detailed field observations, ages, and geochemistry for newly identified high-Mg diorites and A-type rhyolites in the central NAOB. We use these data to address the petrogenesis of the high-Mg diorites and A-type rhyolites, and to elucidate the subduction history of the Proto-Tethys Ocean.

## 2. Regional geology

The Altun Orogenic Belt (AOB) is an important section of the Central China Orogenic Belt that lies between the Tarim to the north and the Kunlun Mountains and Qaidam to the south (Fig. 1a). The AOB consists of four E-W trending, subparallel tectonic units from north to south: (1) the northern Altun Archean complex zone (locally known as the North Altun terrane or Dunhuang block; Zhang et al., 2014), (2) the NAOB (previously called the northern Altun oceanic subduction-collision complex; Liu et al., 2012), (3) the central Altun block (CAB), and (4) the southern Altun continental subduction-collision complex zone that contains high- to ultrahigh-pressure and ophiolitic rocks (Liu et al., 2009) (Fig. 1b).

The NAOB extends ~300 km from east to west. It consists of high-pressure metamorphic rocks, ophiolites, mafic and felsic igneous rocks, and volcano-sedimentary sequences (Fig. 1c). The volcano-sedimentary sequence crops out along the NAOB, and is known as the Lapeiquan Formation (Group; Xinjiang BGMR, 2006). Previous investigations have suggested that the Lapeiquan Formation is an Ordovician (Xinjiang BGMR, 2006) or Mesoproterozoic sequence (Xinjiang

**Fig. 2.** (a) Geologic map of the Dawan area, North Altyn Orogenic Belt (modified after Xinjiang BGMR, 2006); Simplified stratigraphic cross section of middle Lapeiquan Formation (b) and upper Lapeiquan Formation (c). The number and the star show the sample number and the sampling locality, the marked age data are from Han et al. (2012) and Ye et al. (2018).

BGMR, 1981); however, recent zircon U-Pb ages from rhyolites (485–495 Ma) indicate a late Cambrian age (Wang et al., 2019; Ye et al., 2018). The ophiolites occur scarcely between the Lapeiquan and Hongliugou areas, and consist mainly of serpentinized peridotite, cumulates (wehrlite, anorthosite, gabbro, and plagiogranite), basalts, and silicalites (Yang et al., 2008). The cumulates yield zircon U-Pb ages of 520–480 Ma (Gai et al., 2015; Yang et al., 2008), and the ophiolites are thought to be formed in a supra-subduction zone (Yang et al., 2008). The high-pressure metamorphic rocks are blueschists and eclogites that were metamorphosed at 510–490 Ma, and occur as tectonic blocks in the subduction-accretion complex (Zhang et al., 2010). The mafic intrusions yield ages of 520–460 Ma and are sparsely distributed along the NAOB (Ye et al., 2018). The granitic rocks in this area can be divided into two groups, i.e., ~520–470 Ma subduction-related group (mainly I-type granites) and ~450–410 Ma post-orogenic group (I- and S-type granites and adakitic rocks) (Han et al., 2012; Liu et al., 2016b, 2017a; Wu et al., 2009). The assemblage of high-pressure metamorphic rocks, ophiolites, subduction-accretion complex, and arc igneous rocks suggest that the NAOB was an early Paleozoic accretionary orogenic belt (Meng et al., 2017; Zhang et al., 2017).

### 3. Petrography

#### 3.1. Baijianshan diorites

The Baijianshan pluton was intruded into the lower member of the Lapeiquan Formation, and is in fault contact with Carboniferous

sedimentary rocks (Xinjiang BGMR, 2006) (Fig. 2a, 4a). Baijianshan pluton covers an area of  $\sim 6 \times 1 \text{ km}^2$  and consists of homogeneous gray medium-grained inequigranular diorite (Fig. 4b, f, g). Primary minerals include plagioclase (45–50 vol.%), amphibole (50–55 vol.%), quartz (1–3 vol.%), and minor clinopyroxene and biotite (< 2 vol.%). Accessory minerals include Fe-Ti oxides, zircon and apatite. The diorites have experienced variable degrees of alteration, as shown by the sericitization of some plagioclases and replacement of hornblende by chlorite and epidote. One sample of the Baijianshan pluton (16BJS04: 39°08'33" N, 91°50'48" E) was collected for age dating and four for geochemical analyses.

#### 3.2. Dawanbei and Dabanxi rhyolites

The lower-greenschist-facies early Paleozoic volcano-sedimentary Lapeiquan Formation crops out mainly in the Beiketian, Goukouquan, Dawan (Kaladawan), Baijianshan, and Lapeiquan regions (Fig. 1c; Xinjiang BGMR, 2006; Ye et al., 2018). To the north, it is in contact with Precambrian basement along the North Altyn fault, and to the south, it is in contact with the Paleogene Gancaigou Formation along a thrust fault (Fig. 1b, c). The Lapeiquan Formation can be subdivided into lower, middle and upper members (Fig. 2a). The lower member (LMF) consists mainly of meta-volcanic and meta-volcanoclastic rocks, including trachyandesites, basalts, siltstones and sandy slate (Xinjiang BGMR, 2006). The middle member (MMLF) is composed mainly of bimodal volcanic rocks (basalts and rhyolites/rhyodacite) with minor sandstone and sericite-chlorite schists (Fig. 2b, 3; Xinjiang BGMR, 2006), and the upper member

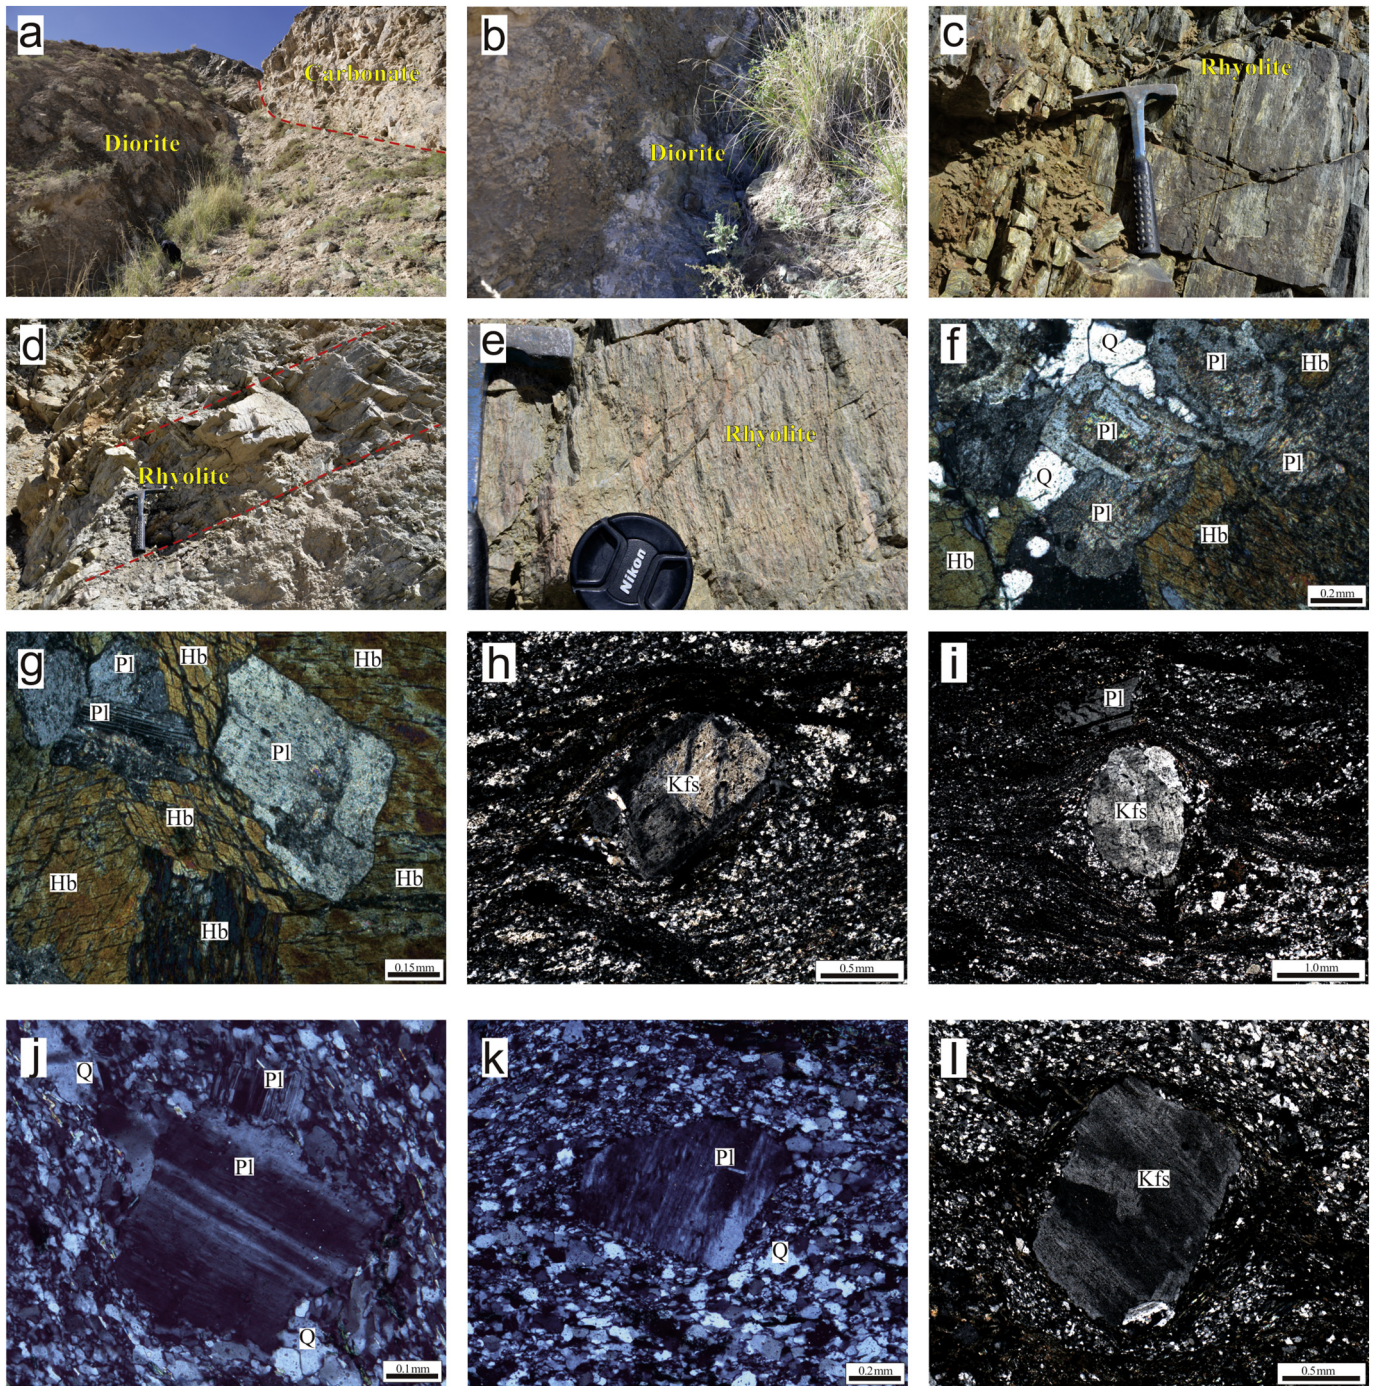

Fig. 3. Measured section of the middle member and upper member of Lapeiquan Formation (data are from Xinjiang BGMR, 2006)

(UMLF) consists mainly of clastic rocks, cherts and carbonates, with minor meta-volcanic rocks (Fig. 2c, 3; Xinjiang BGMR, 2006; Ye et al., 2018). The volcano-sedimentary sequence of MMLF and UMLF extends for >100 km between the Qiongtag to Lapeiquan areas. Lower-greenschist-facies metamorphic minerals like sericite, chlorite, and biotite are commonly observed in most rocks.

Eight rhyolites for elemental analyses were chosen from the MMLF (Fig. 2a, b, 4c). Two rhyolite samples (16DBX01: 39°03' 55"N, 91°42'36"E; 16DBX03: 39°04'12"N, 91°42'36"E) for zircon U–Pb dating and 11 rhyolite samples for geochemical analysis (Fig. 2a, c, 4d, e) were collected from the UMLF. All rhyolite samples were from fresh outcrops. We observed flow structures in the rhyolites from field observations and thin sections (e.g., Fig. 4c, e).

**Fig. 4.** Field photographs and photomicrographs of the Baijianshan diorites, Dawanbei and Dabanxi rhyolites. (a) The Baijianshan diorites intruded carbonate rocks; Field outcrop of the Baijianshan diorites (b) and Dawanbei rhyolites from the middle member of Lapeiquan Formation (c); (d, e) Interbedded layer rhyolites from the upper member of Lapeiquan Formation; (f, g) Euhedral plagioclase and amphibole in the thin section of the Baijianshan diorites (cross nicols); Phenocrysts and flow structure in the thin section of the Dawanbei rhyolites (h, i) and the Dabanxi rhyolites (j-l) (cross nicols). Abbreviations: Hb, hornblende; Kfs, K-feldspar; Pl, plagioclase; Q, quartz.

The rhyolites are pink-gray and porphyritic, and contain phenocrysts of quartz, perthite, and feldspar (20–25 vol.%) in a fine-grained groundmass (Fig. 4h–l). The matrix is composed of equigranular quartz (<0.05 mm; 50–60 vol.%), K-feldspar (15–20 vol.%), and biotite (2–5 vol.%) crystals (Fig. 4h–l).

#### 4. Analytical methods

Zircon was separated first using magnetic and heavy liquid techniques, then hand-picking under a binocular microscope.

Zircon grains were mounted in epoxy disks, which were polished to the approximate centers of the zircon grains. Cathodoluminescence (CL) images and transmitted light micrographs were obtained to investigate the internal structures. The three zircon samples were analyzed using laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) method at Tianjin Institute of Geology and Mineral Resources, China Geological Survey (TIGMR, CGS). The laser beam diameter was set to be ~32  $\mu\text{m}$  with a frequency of 10 Hz. Zircon 91500 and GJ-1 and glass NIST 610 were used as external standards. The analytical procedures

Chondrite uniform reservoir (CHUR) values ( $^{147}\text{Sm}/^{144}\text{Nd} = 0.1967$ ,  $^{143}\text{Nd}/^{144}\text{Nd} = 0.512638$ ) are used for the calculation.  $\lambda_{\text{Sm}} = 6.54 \times 10^{-12} \text{ year}^{-1}$  (Lugmair and Harti, 1978). The  $(^{143}\text{Nd}/^{144}\text{Nd})_i$ ,  $\epsilon_{\text{Nd}}(t)$  of the 16BJS04, 16DWB and 16DBX were calculated using age of 536 Ma, 495 Ma and 495 Ma, respectively. The two-stage model age ( $T_{\text{DM}}^c$ ) calculations are given by Jahn et al., 1999.

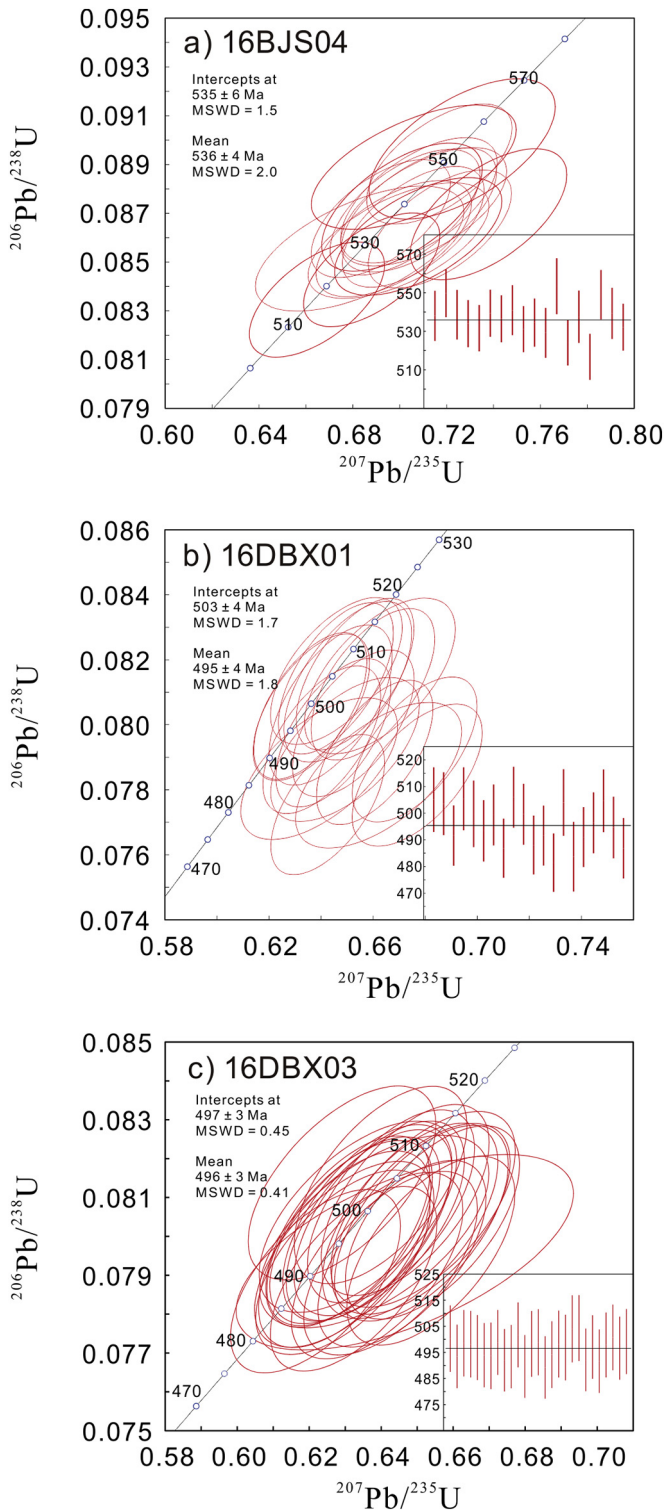

**Fig. 5.** Representative CL images of zircon from the Baijianshan diorites (16BJS04), Dawanbei rhyolites (16AB02) from the middle Lapeiquan Formation, and the Dabanxi rhyolites (16DBX02 and 16DBX03) from the upper Lapeiquan Formation. Analytical spots, ages and  $\epsilon_{\text{Hf}}(t)$  are shown (see details in the text).

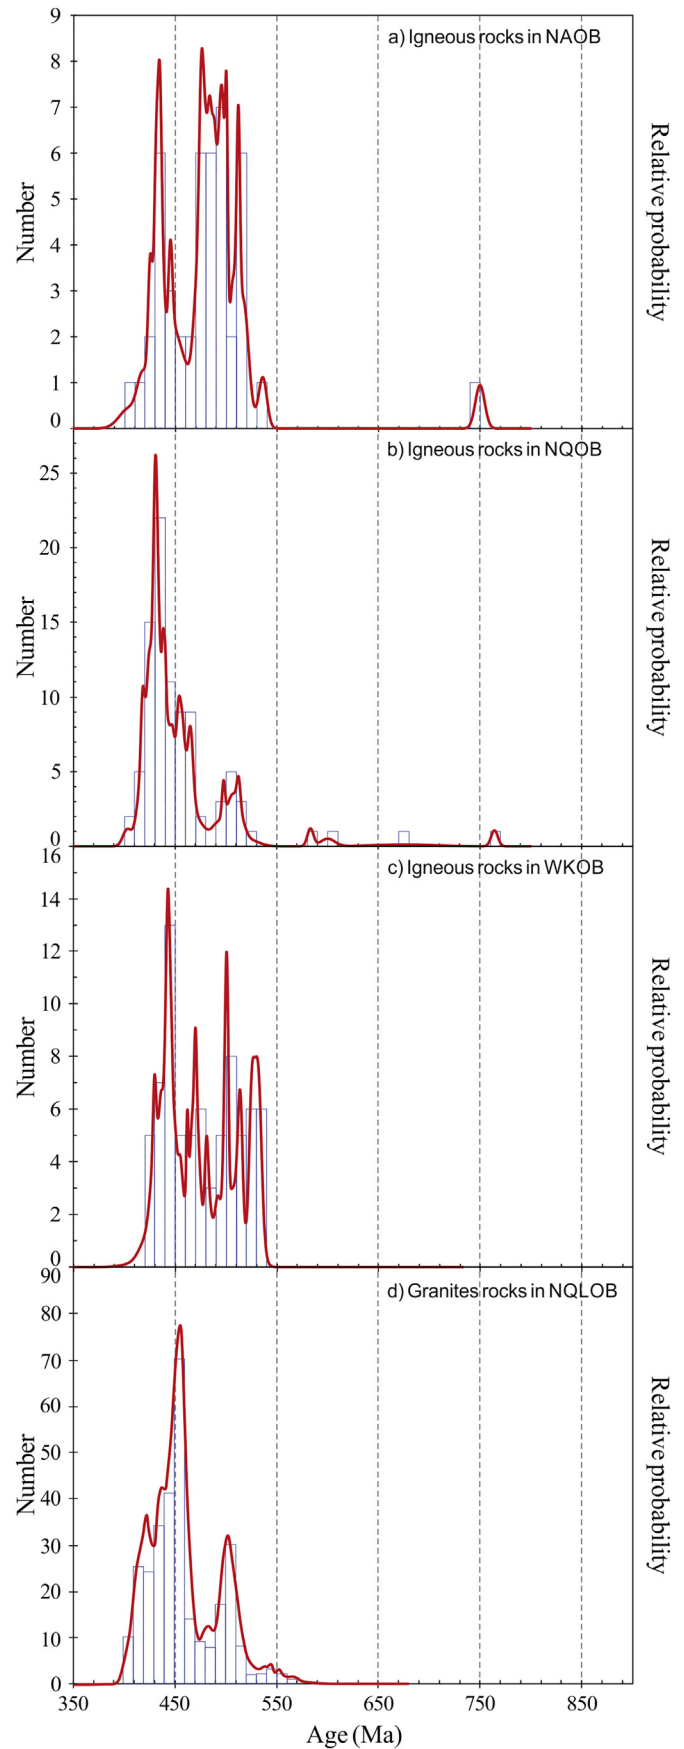

were given by Geng et al. (2011). ICPMSDataCal and Isoplot/Ex 3.23 were used for data reduction (Liu et al., 2010) and processing (Ludwig, 2003), respectively. The age data are presented in Appendix Table I.

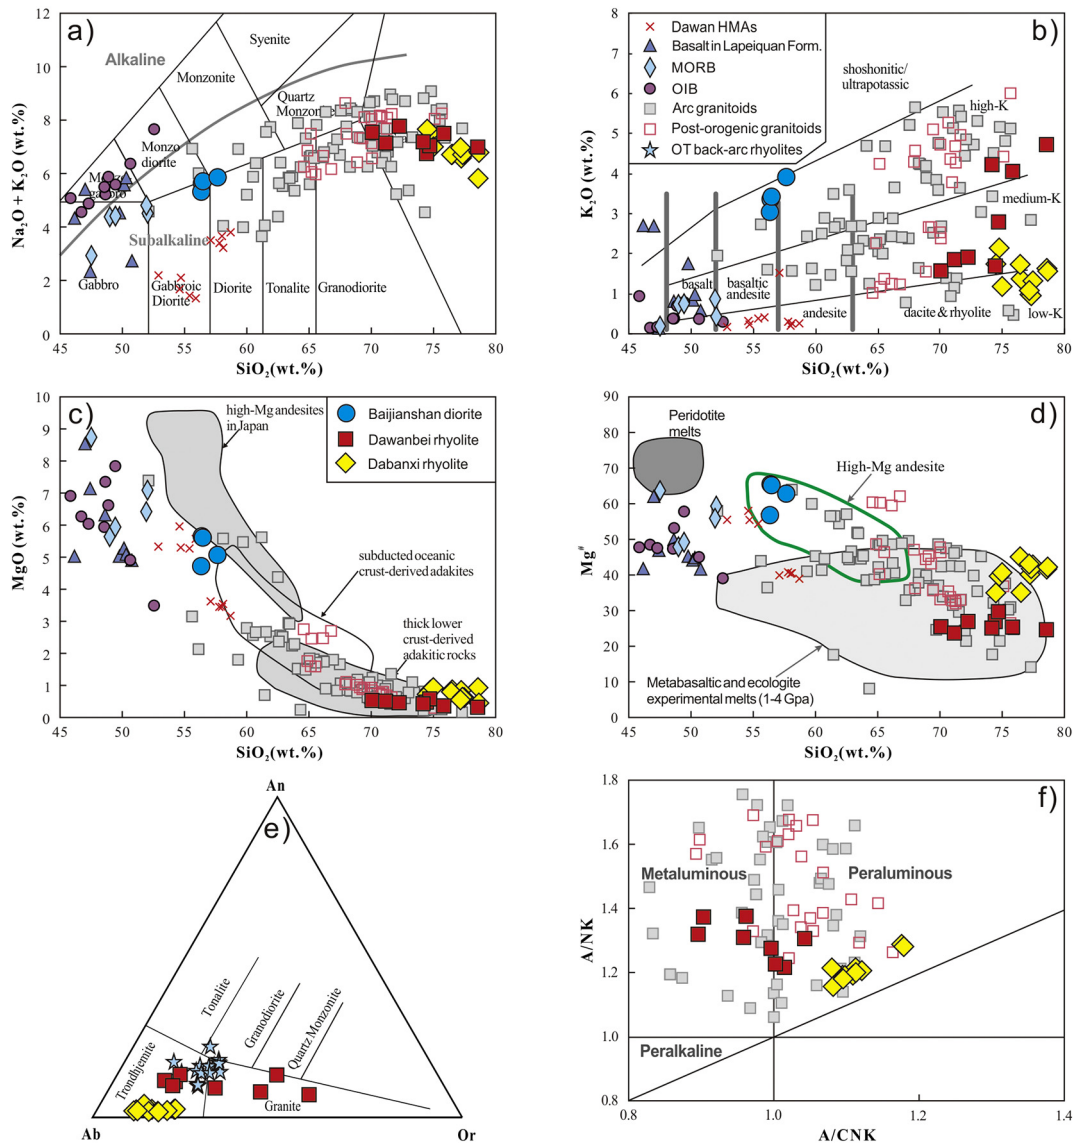

Zircon Hf isotopes were measured on a New-Wave-193 nm ArF-excimer laser ablation system linking to a Thermo Scientific Neptune multi-collector ICP-MS (LA-MC-ICP-MS) at the TIGMR, CGS. Analyses utilized a laser repetition rate of 10 Hz, power of 100mj, and a spot

**Fig. 6.** Concordia plots of U-Pb zircon data for zircons from the Baijianshan diorites (a) and Dabanxi rhyolites (b, c).

**Fig. 7.** Histogram of zircon U-Pb ages for igneous rocks (age data for North Altun are from Ye et al., 2018; Zheng et al., 2019 and references therein, rth Qilian are from Yang et al., 2018 and references therein, West Kunlun Orogenic Belt are from Li et al., 2018b; Liu et al., 2019 and references therein; North Qinling Orogenic Belt are from Liu et al., 2016a; Zhang et al., 2013).

**Fig. 8.** (a)  $\text{SiO}_2\text{-Na}_2\text{O} + \text{K}_2\text{O}$  plot (Middlemost, 1994); (b)  $\text{SiO}_2\text{-K}_2\text{O}$  plot (Peccerillo and Taylor, 1976); (c)  $\text{SiO}_2$  versus  $\text{MgO}$  diagram; (d)  $\text{SiO}_2$  versus  $\text{Mg}^\#$  diagram; (e) Normative feldspar classification from O'Connor (1965); (f)  $\text{A}/\text{NK}$  versus  $\text{A}/\text{CNK}$  diagram.  $\text{A} = \text{Al}_2\text{O}_3$ ,  $\text{N} = \text{Na}_2\text{O}$ ,  $\text{K} = \text{K}_2\text{O}$ ,  $\text{C} = \text{CaO}$  (all in molar proportion). Data for peridotite melts are from Stern and Kilian (1996), metabasaltic and eclogite experimental melts (1–4.0 GPa) are from Rapp et al. (1999) and references therein. Data for high-Mg andesites of SW Japan are from the following references: Shimoda et al. (1998), Tatsumi et al. (2006) and references therein. Data for the Okinawa Trough back-arc rhyolites are from Shinjo and Kato, (2000). Data for Dawan high-Mg andesites (HMAs) are from Ye et al. (2018), arc basalts are from Hao et al. (2013), MORBs are from Wu et al. (2002), OIBs are from Meng et al., 2010, arc granitoids are from Liu et al., 2017, Meng et al. (2017), Zheng et al. (2019), post-orogenic granitoids are from Wu et al., 2009, Yu et al., 2018, the Okinawa Trough back-arc basin rhyolites are from Shinjo and Kato (2000).

size of 60  $\mu\text{m}$ . Instrumental parameters and data acquisition were similar to those documented in Geng et al. (2011). Zircon Hf isotopic compositions are listed in Appendix Table II.

Whole-rock major and trace element compositions were determined by a Rigaku ZSX100e XRF and PerkinElmer ELAN DRC-e ICP-MS at the State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences (CAS), following Li et al. (2002) and Qi et al. (2000), respectively. The analytical precision was better than 5% for major elements and 10% for most trace elements, and the results are reported in Table 1.

Samples for Nd isotopic analysis were dissolved in mixture of HF,  $\text{HNO}_3$  and  $\text{HClO}_4$  in Teflon bombs, then separated using conventional cation-exchange techniques. The isotopic measurements were performed on a Thermo Scientific Triton thermal ionization mass spectrometer (TIMS) at the TIGMR, CGS. Mass fractionation corrections for Nd isotope ratios assumed a  $^{146}\text{Nd}/^{144}\text{Nd}$  ratio of 0.7219. The mean

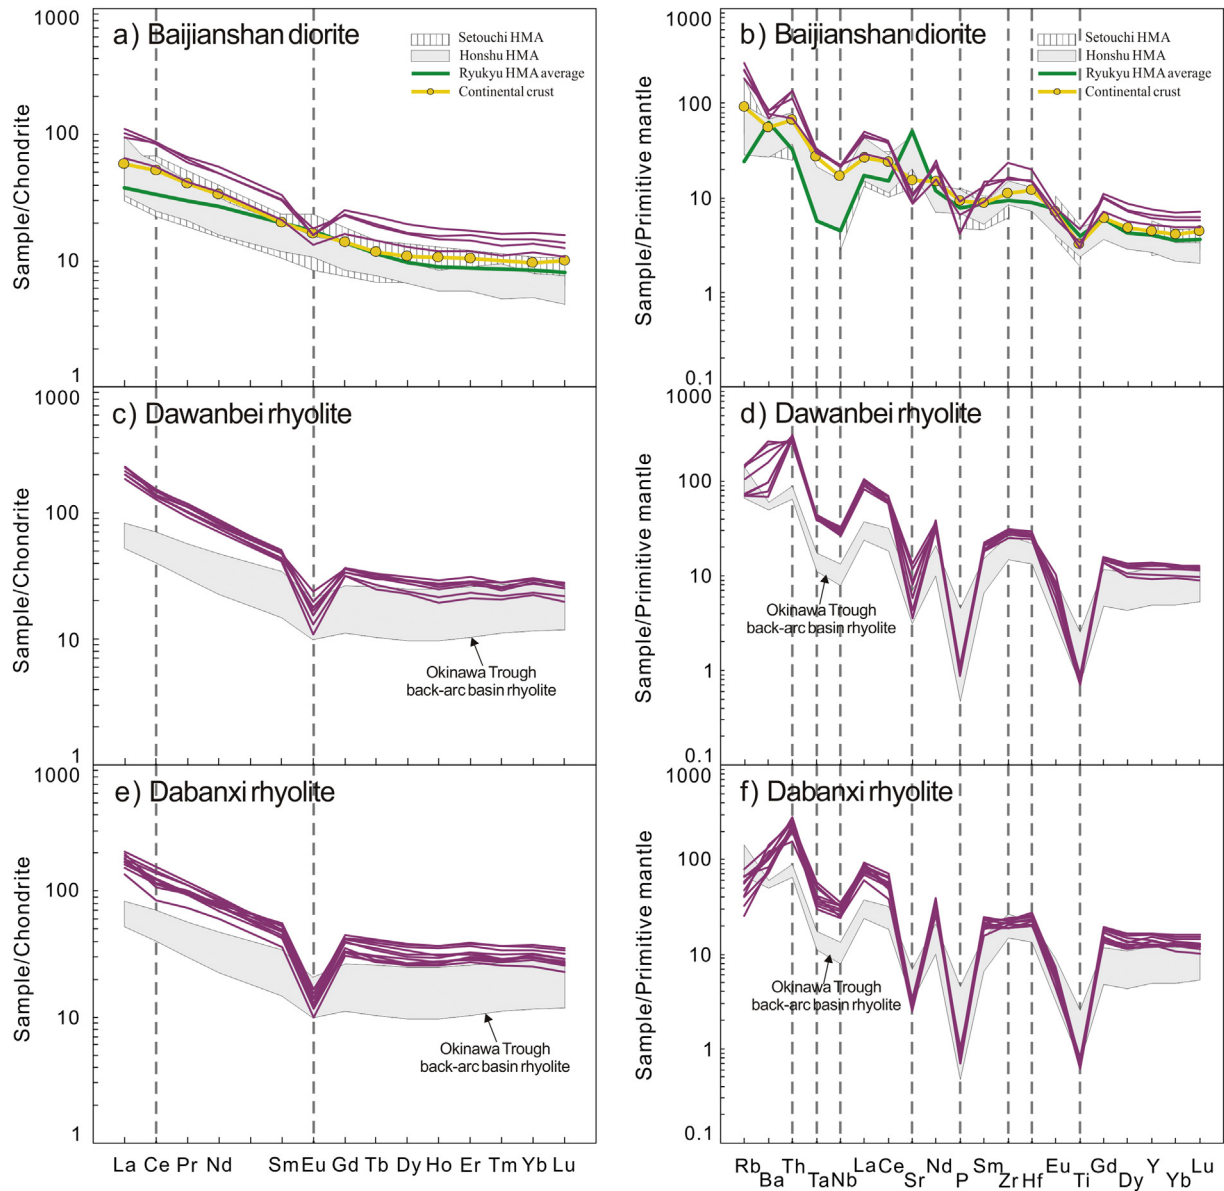

$^{143}\text{Nd}/^{144}\text{Nd}$  ratio measured for the USGS BCR-2 standard was  $0.512645 \pm 5$  ( $2\sigma$ ). Analytical results are listed in Table 2.

## 5. Results

### 5.1. U-Pb zircon geochronology

#### 5.1.1. Baijianshan diorites

Sample 16BJS04 contains euhedral zircon grains 80–110  $\mu\text{m}$  in length, with length-to-width ratios of 1:1 to 2:1. All grains are colorless, with oscillatory growth zoning in CL images (Fig. 5). 16 zircon grains were analyzed, which yield variable U (196–800 ppm) and Th (176–1000 ppm) contents and Th/U ratios of 0.59–1.54 (Appendix Table I). All analyses yield nearly concordant ages, with a weighted mean  $^{206}\text{Pb}/^{238}\text{U}$  age of  $536 \pm 4$  Ma (MSWD = 2.0; Fig. 6a). We interpret this as the crystallization age of the Baijianshan diorite pluton.

**Fig. 9.** Chondrite-normalized rare earth element (REE) patterns and primitive mantle-normalized trace-element spider diagrams for the Baijianshan diorites (a, b), Dawanbei rhyolites (c, d) and Dabanxi rhyolites (e, f). Chondrite-normalizing values are from Boynton (1984), primitive mantle-normalizing values are from Sun and McDonough (1989). Data for continental crust are from Rudnick and Gao, 2003, the Setouchi, Honshu, Ryuku HMAs are from Tatsumi et al. (2006) and references therein, the Okinawa Trough back-arc rhyolites are from Shinjo and Kato (2000).

### 5.1.2. Dawanbei and Dabanxi rhyolites

Zircon grains from samples 16DBX01 and 16DBX03 are clear, euhedral, with obvious zoning, and are 60–120  $\mu\text{m}$  long with length-to-width ratios of 1:1–3:1 (Fig. 5). A total of 20 analyses from 16DBX01 yield U and Th contents of 373–2051 ppm and 152–2259 ppm, respectively, with Th/U ratios of 0.36–1.10 (Appendix Table I). They yield consistent  $^{206}\text{Pb}/^{238}\text{U}$  ages with a weighted mean age of  $495 \pm 4$  Ma (MSWD = 1.8; Fig. 6b). Zircons from sample 16DBX03 have varying Th (77–398 ppm) and U (244–787 ppm) contents, with Th/U ratios of 0.31–0.59 (Appendix Table I). All 28 analyses from 16DBX03 defined a good concordia diagram with a weighted mean  $^{206}\text{Pb}/^{238}\text{U}$  age of  $496 \pm 3$  Ma (MSWD = 0.41; Fig. 6c), which is consistent with sample 16DBX01. Thus, we suggest a crystallization age of  $\sim 495$  Ma for the rhyolites.

We integrate our new data with previous geochronological data (Zheng et al., 2019 and references therein) and identify five main phases

of magmatism in the NAOB at  $\sim 750$  Ma,  $\sim 530$  Ma,  $\sim 520$  Ma,  $\sim 485$ – $475$  Ma and  $\sim 430$  Ma (Fig. 7a). These five age peaks are similar to those found in the North Qilian (Fig. 7b), West Kunlun (Fig. 7c), and North Qinling (Fig. 7d) Orogenic Belts.

## 5.2. Whole-rock geochemistry

### 5.2.1. Baijianshan diorites

The diorite samples yield a narrow range of  $\text{SiO}_2$  (56.34 to 57.65 wt.%) and  $\text{Na}_2\text{O} + \text{K}_2\text{O}$  (5.32 to 5.86 wt.%) contents, and plot at the boundary between gabbroic diorites and diorites on a total alkali-silica (TAS) diagram (Fig. 8a; Middlemost, 1994). They have high MgO contents (4.72–5.26 wt.%) and  $\text{Mg}^\#$  values (57–65), and low  $\text{Fe}_2\text{O}_3^\text{T}$  contents (5.90–6.22 wt.%), and exhibit high-K calc-alkaline trend on a  $\text{SiO}_2$ - $\text{K}_2\text{O}$  diagram (Fig. 8b). On  $\text{SiO}_2$ -MgO and  $\text{SiO}_2$ - $\text{Mg}^\#$  diagrams, the samples plot close to the

high-Mg andesites in the Setouchi Volcanic Belt (SVB), Japan (Fig. 8d; Tatsumi et al., 2006).

The Baijianshan diorites have total rare earth element (REE) contents of 112–171 ppm, with enrichment in light REE (LREE) relative to heavy REE (HREE;  $La_N/Yb_N = 5.7\text{--}8.2$ ) and moderately

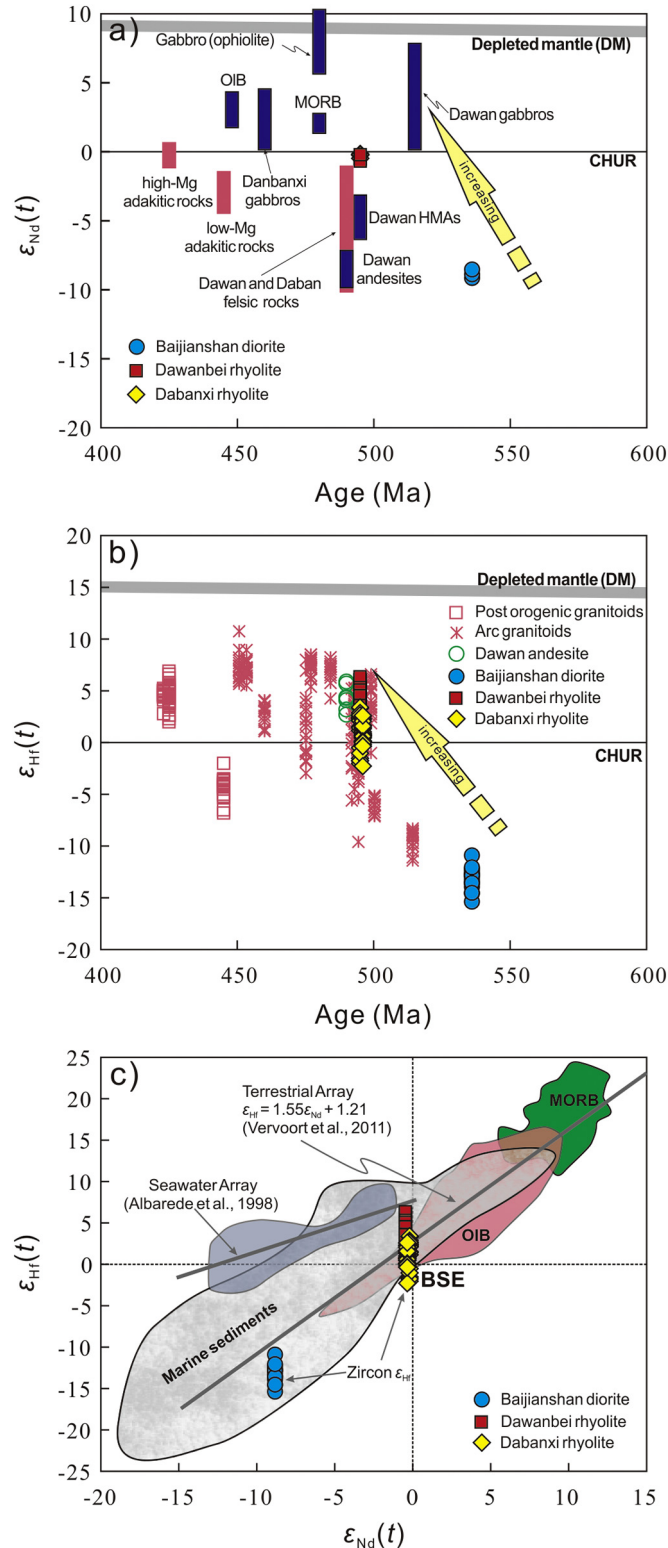

Fig. 10. Zircon age versus whole-rock  $\epsilon_{Nd}(t)$  (a) and zircon  $\epsilon_{Hf}(t)$  (b) diagram; (c) whole-rock  $\epsilon_{Nd}(t)$  versus zircon  $\epsilon_{Hf}(t)$  diagram. The data sources are the same as Fig. 6.

negative Eu anomalies ( $Eu/Eu^* = 0.55\text{--}0.72$ ; Fig. 9a). The Baijianshan diorites are enriched in large ion lithophile elements (LILE; e.g. Rb and Ba) and depleted in high field strength elements (HFSE) with significant Nb-Ta troughs (Fig. 9b). In addition, they have high Y (23.3–34.4 ppm) and low Sr (182–234 ppm) contents, leading to low Sr/Y ratios (5.4–8.4), distinct from those of adakitic rocks (Defant and Drummond, 1990).

The Baijianshan diorites contain lower concentrations of Cr (15.3–47.1 ppm) and Ni (18.7–28.3 ppm) than expected for high-Mg andesites (e.g. Tatsumi et al., 2006), indicating the diorites have undergone various degrees of fractionation crystallization. Decreasing MgO and  $Mg^{\#}$  contents with increasing  $SiO_2$  contents (Fig. 8c, d) suggest the fractionation of olivine, which is in agreement with the negative correlation of Cr and Ni with  $SiO_2$  (Figures not shown). Furthermore, the low Cr and Ni abundances may also indicate the fractionation crystallization of Cr- and Ni-bearing minerals (e.g. spinel, Fe-Ni sulfide). The variations in  $Eu/Eu^*$  versus Sr, coupled with negative Eu and Sr anomalies (Fig. 9a, b), indicate extensive fractionation of plagioclase. Besides, the Baijianshan diorites define an amphibole fractionation trend on a  $SiO_2$  versus Dy/Yb diagram.

### 5.2.2. Dawanbei and Dabanxi rhyolites

The Dawanbei and Dabanxi rhyolites have  $SiO_2$  contents of 70.07–78.65 wt.%, and most have high  $Na_2O$  (4.19–5.97 wt.%) contents with  $Na_2O/K_2O$  ratios of 1.52–6.06, except three samples have lower  $Na_2O$  (2.27–3.45 wt.%) contents with  $Na_2O/K_2O$  ratios ranging from 0.48 to 0.82 (Table 1). On the TAS and  $SiO_2$ – $K_2O$  diagrams, most samples plot in the low-K and medium-K calc-alkaline fields (Fig. 8a, b). The rhyolites plot in the trondjemite field on a normative anorthite–albite–orthoclase ternary diagram (Fig. 8e). The Dawanbei and Dabanxi rhyolites also have low MgO (0.32–0.93 wt.%),  $TiO_2$  (0.13–0.19 wt.%)  $Al_2O_3$  (10.25–14.38 wt.%), and  $P_2O_5$  (0.02 wt.%) contents, and high  $Fe_2O_3^T$  (1.22–3.25 wt.%) contents, with low  $Mg^{\#}$  (24–45). The samples are metaluminous to weakly peraluminous, with A/CNK values of 0.89–1.16 (Fig. 8f).

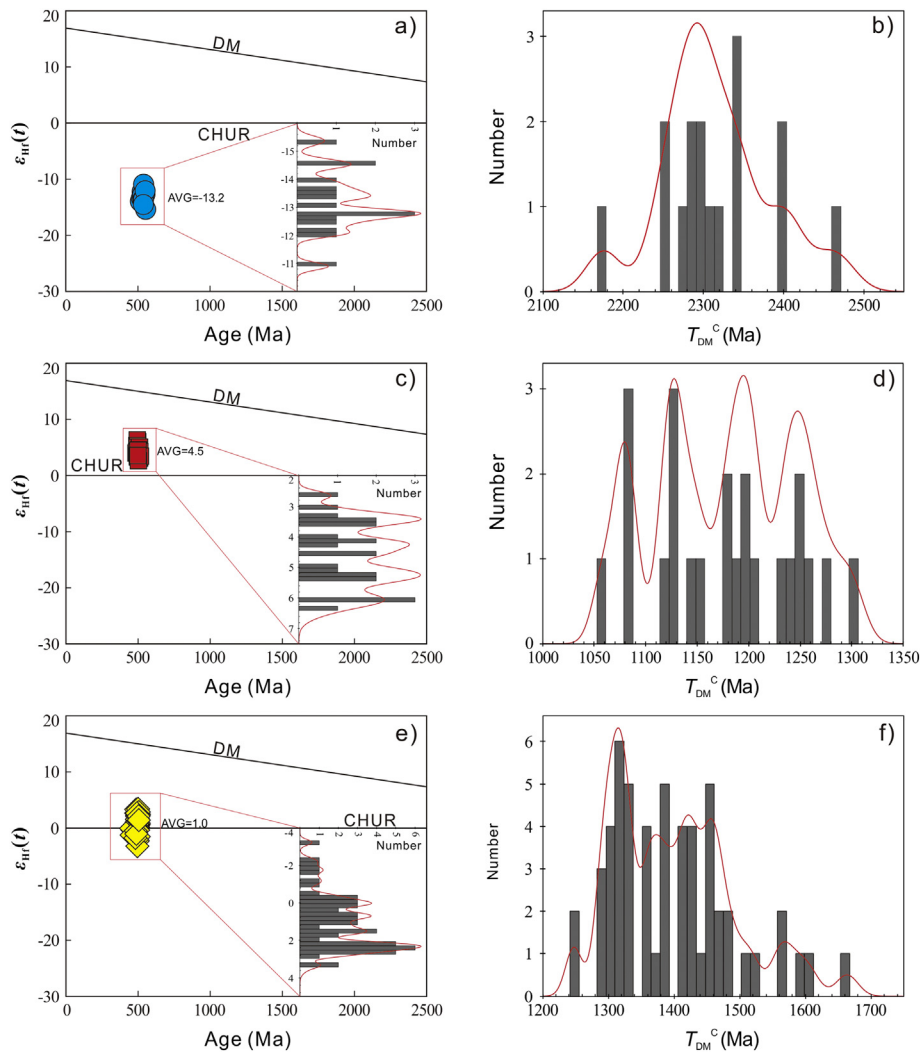

Despite the variation in their major-element contents, the rhyolites display coherent normalized REE and trace element patterns. The rhyolites have high total REE contents (176–308 ppm; Table 1) and show LREE-enriched patterns ( $La_N/Yb_N = 4.2\text{--}8.6$ ), pronounced negative Eu anomalies ( $Eu/Eu^* = 0.29\text{--}0.58$ ), and relatively flat HREE patterns ( $Gd_N/Yb_N = 1.03\text{--}1.44$ ; Fig. 9c, e). The rhyolites show significant troughs of Nb, Ta, and Sr on primitive-mantle-normalized trace element diagrams (Fig. 9d, f). Notably, REE and trace element compositions of the Dawanbei and Dabanxi rhyolites are similar to those of Okinawa Trough back-arc basin rhyolites (Table 1; Fig. 9e, f; Shinjo and Kato, 2000).

### 5.3. Whole-rock Nd isotopic compositions

The Nd isotopic compositions representative rocks are presented in Table 2. Baijianshan diorite pluton samples have constant  $^{147}Sm/^{144}Nd$  (0.1177–0.1199) and  $^{143}Nd/^{144}Nd$  (0.511900–0.511924) ratios, corresponding to a narrow range of initial  $^{143}Nd/^{144}Nd$  ratios (0.511479–0.511511),  $\epsilon_{Nd}(t)$  values (–9.1 to –8.5; Fig. 10a), and two-stage model ages ( $T_{DM}^c$ ; 1998–1948 Ma). The Nd isotopic compositions of the Dawanbei and Dabanxi rhyolites are similar to each other: they have  $^{147}Sm/^{144}Nd$  ratios of 0.1106–0.1282 and  $^{143}Nd/^{144}Nd$  ratios of 0.512339–0.512403, with  $\epsilon_{Nd}(t)$  values of –0.2 to –0.7 (Fig. 10a) and a narrow range of  $T_{DM}^c$  (1285–1209 Ma).

### 5.4. Zircon Lu–Hf isotopes

Zircons grains from the Baijianshan diorites have initial  $^{176}Hf/^{177}Hf$  ratios of 0.282024–0.282138, which yield a small range of  $\epsilon_{Hf}(t)$  values (–15.4 to –10.9, weight mean = –13.2; Fig. 10b, 11a). The two-stage Hf

**Fig. 11.** Zircon age versus zircon  $\varepsilon_{\text{Hf}}(t)$  (histograms of zircon  $\varepsilon_{\text{Hf}}(t)$  insert) and histograms of  $T_{\text{DM}}^{\text{C}}$  for the Baijianshan diorites (a, b), Dawanbei rhyolites (c, d) and Dabanxi rhyolites (e, f).

model ages ( $T_{\text{DM}}^{\text{C}}$ ) are 2463–2176 Ma, with a weighted mean age of 2314 Ma (Fig. 11b).

The  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios of zircons from the Dawanbei rhyolites range from 0.282555 to 0.282666, and their  $^{176}\text{Lu}/^{177}\text{Hf}$  ratios are low ( $-0.002$ ). The zircon  $\varepsilon_{\text{Hf}}(t)$  values are 2.6 to 6.4 (Fig. 10b), with a weight mean of 4.5 (Fig. 11c). The Hf model ages range from 1059 Ma to 1299 Ma (Fig. 11d).

The zircon grains from the Dabanxi rhyolites have  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios of 0.282433–0.282581, which correspond to initial  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios of 0.282397–0.282563 and  $\varepsilon_{\text{Hf}}(t)$  values of  $-2.3$  to  $+3.4$  (weight mean =  $+1$ ; Fig. 9e, 10b). The Hf model ages are 1606–1245 Ma (Fig. 11f). On an  $\varepsilon_{\text{Nd}}(t)$  versus  $\varepsilon_{\text{Hf}}(t)$  diagram, the diorites and rhyolites show broadly coupled whole-rock Nd and zircon Hf isotopic compositions (Fig. 10c).

## 6. Discussion

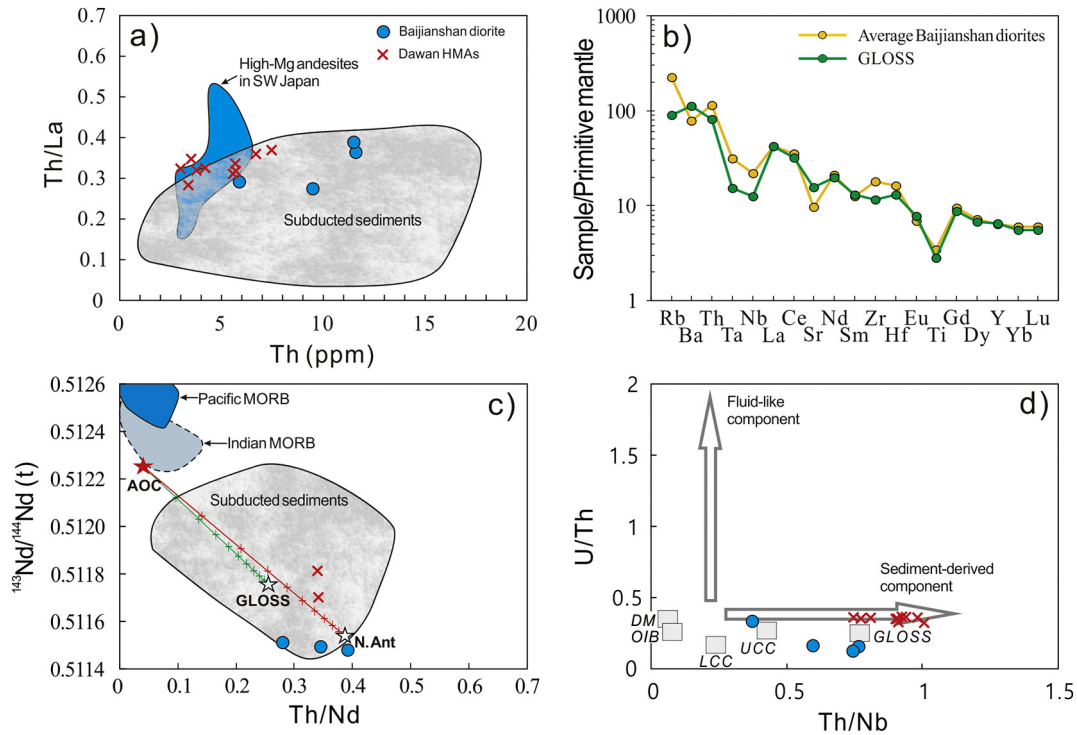

### 6.1. Petrogenesis of the Baijianshan diorites

The Baijianshan high-Mg diorites have crustal-like trace element patterns (Fig. 9b, d) and enriched whole-rock Nd and zircon Hf isotopic compositions (Fig. 10a, b), indicating contribution of continental component to their petrogenesis, related to either

source variation or crustal contamination during magma fractionation (e.g. Jahn et al., 1999). However, the following lines of evidence argue against the view of crustal assimilation: (1) the constant whole-rock Nd and zircon Hf isotopic compositions (Table 2), (2) the large range of Nb/La ratios but constant Nb/Th ratios in most samples (Table 1), and (3) the absence of xenocrystic zircons (e.g. Yang et al., 2019; Fig. 5; Appendix Table I). The limited extent of crustal contamination means that the geochemical characteristics of the Baijianshan diorites directly reflect their source and tectonic environment.

High-Mg andesites and diorites could be generated by a variety of processes, including partial melting of hydrous peridotite (Hirose, 1997; Straub et al., 2011; Wang et al., 2014), partial melting of lower continental crust and interaction with overlying mantle through delamination (Gao et al., 2004; Wang et al., 2006), mixing between mantle-derived mafic and crust-derived felsic magmas at crustal-level (Qian and Hermann, 2010; Shellnutt and Zellmer, 2010), and interactions between subducted sediments or slab melts and peridotite in the mantle wedge (Tatsumi, 2001; Wang et al., 2011).

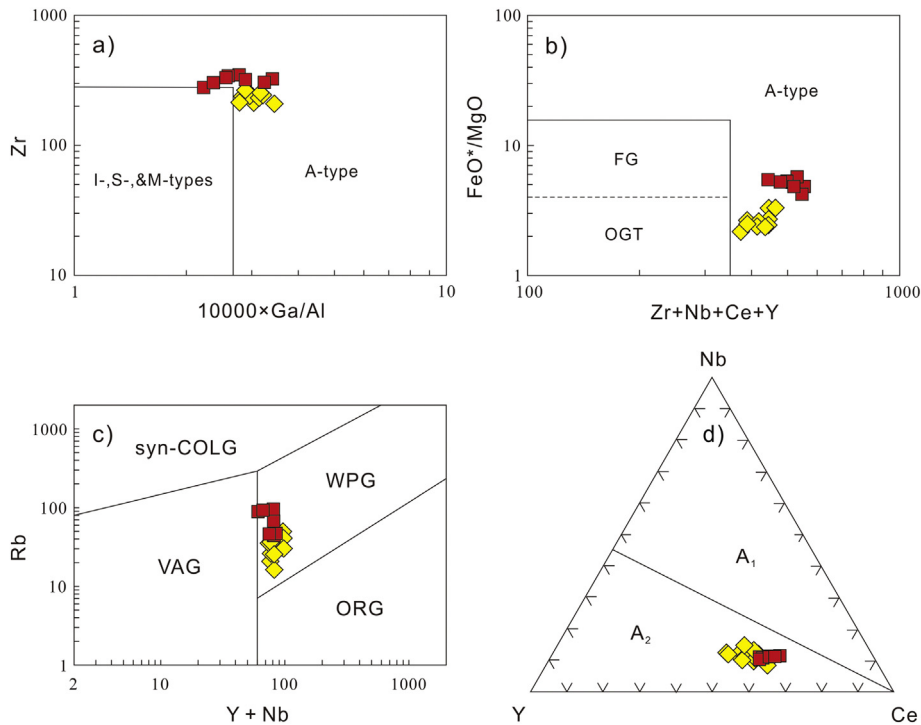

Experimental studies have demonstrated that partial melting of the hydrous mantle peridotite at temperatures below 1100 °C at 1 GPa can produce high-Mg andesitic melt with low  $\text{FeO}^{\text{T}}$  (4.04–5.36 wt.%) and

**Fig. 12.** (a) Th versus Th/La diagram for the Baijianshan diorites; (b) Primitive mantle-normalized trace-element spider diagrams for the Baijianshan diorites and GLOSS; (c) Plot of Th/Nd versus  $^{143}\text{Nd}/^{144}\text{Nd}(t)$ ; (d) Th/Nb versus U/Th diagrams for the Baijianshan diorites. Data for GLOSS and subducted sediments are from [Plank and Langmuir \(1998\)](#), other data sources are same as Fig. 6.

$\text{TiO}_2$  (0.55–0.70 wt.%), and high CaO (8.53–9.99 wt.%) and  $\text{Al}_2\text{O}_3$  (17.2–21.7 wt.%) contents ([Hirose, 1997](#); [Rapp et al., 1999](#)). In this scenario, high-Mg diorites commonly contain dunite xenoliths and high-Fo olivine xenocrysts (e.g. [Qian and Hermann, 2010](#)). The absence of

olivine xenocrystal and dunite xenoliths, combined with high  $\text{Al}_2\text{O}_3$  (16.04–16.44 wt.%), low CaO (4.94–5.68 wt.%) and negative  $\varepsilon_{\text{Nd}}(t)$  values indicate that the Baijianshan diorites were not generated from partial melting of hydrated peridotite.

**Fig. 13.** (a)  $10000 \times \text{Ga}/\text{Al}$  versus Zr and (b)  $(\text{Zr} + \text{Nb} + \text{Ce} + \text{Y})$  versus  $\text{FeO}^*/\text{MgO}$  discrimination diagrams of [Whalen et al. \(1987\)](#), indicative of the Dawanbei and Dabanxi rhyolites are A-type granites. (c) Y + Nb versus Rb diagram of [Pearce, 1996](#) showing the Dawanbei and Dabanxi rhyolites plot into the WPG field. (d) Plots of Dawanbei and Dabanxi A-type rhyolites in Nb-Y-Ce triangular diagram of [Eby \(1992\)](#) within the field of  $A_2$ -type granites. FG-fractionated felsic granites, OGT-unfractionated, VAG-volcanic arc granites, ORG-ocean ridge granites, WPG-within-plate granites, syn-COLG-syn-collision granites,  $A_1$ -anorogenic A-type granites,  $A_2$ -post-collisional A-type granites.

The MgO contents and Mg<sup>#</sup> of the diorites are higher than those of experimental melts of metabasalt and eclogite at 1.0–4.0 GPa (Fig. 8c, d; Qian and Hermann, 2013; Rapp and Watson, 1995; Rapp et al., 1999), suggesting that partial melting of delaminated or eclogitic thickened lower continental crust did not generate the Baijianshan diorites, despite their crust-like elemental and isotopic signatures. Partial melting of lower continental crust generally produces adakitic magmas with high Sr and low Y and Yb contents (Qian and Hermann, 2013; Wang et al., 2008). In contrast, the Baijianshan diorites have relatively low Sr (182–234 ppm) and high Y (23.3–34.4 ppm) and Yb (2.41–3.44 ppm) contents. Furthermore, lower continental crust has low U (0.2 ppm) and Th (1.2 ppm) contents (Rudnick and Gao, 2003), unlike the Baijianshan diorites (U=1.43–1.96 ppm, Th=5.88–11.6 ppm).

The relatively uniform whole-rock  $\epsilon_{\text{Nd}}(t)$  and zircon  $\epsilon_{\text{Hf}}(t)$  compositions (Fig. 10a, b) of the Baijianshan diorites are in contrast with those expected for hybrid magmas. Moreover, MORB-like basaltic melts assimilated by crustal melts would require large volumes of continental crust to achieve the enriched Nd–Hf compositions of the Baijianshan diorites, which is impossible given the high MgO contents and Mg<sup>#</sup> of these rocks. The absence of any mafic microgranular enclaves (MMEs) in the Baijianshan diorite pluton also precludes the crustal level magma mixing model.

The following lines of evidence show that interaction between subduction-related components and the overlying mantle wedge can account for the formation of the Baijianshan diorites. (1) The Baijianshan diorites are high-K calc-alkaline and have high K<sub>2</sub>O contents (Fig. 8a, b) resembling high-Mg andesites in the SVB, which were formed by the interaction between subducted sediment-derived melts and peridotites (Tatsumi, 2001; Wang et al., 2011; Yang et al., 2019). (2) The diorites have a crust-like geochemical signature (Fig. 9a, b), enriched whole-rock  $\epsilon_{\text{Nd}}(t)$  and zircon  $\epsilon_{\text{Hf}}(t)$  values (Fig. 10a, b), and their coupled Nd–Hf isotopic compositions that overlap with those of typical marine sediments (Fig. 10c). (3) The Baijianshan diorites have high Th contents and Th/La ratios, which plot in the subducted sediments field on a Th/La versus Th diagram (Fig. 12a). In addition, the Baijianshan diorite composition is similar to that of Global Subducting Sediment (GLOSS; Fig. 12b; Plank and Langmuir, 1998). The low  $\epsilon_{\text{Nd}}(t)$  values and high Th/Nd ratios are also consistent with those of subducted sediments (Fig. 12c), suggesting a major contribution by subducted sediments. (4) The Baijianshan diorites have consistently low U/Th (0.12–0.33) and high Th/Nb (0.37–0.77) ratios, which also support the involvement of a sediment-derived melts rather than of slab-derived fluids (Fig. 12d). According to the evidence above, we argue that the Baijianshan diorites were generated by the melting of subducted sediments and that the melts interacted with peridotites in the mantle wedge.

Three competing mechanisms should be taken into account in explaining the genesis of the Baijianshan high-Mg diorite: (1) mid-ocean ridge subduction (e.g., Sun et al., 2009; Windley et al., 2007), (2) slab break-off (e.g., van Hunen and Allen, 2011) or (3) slab roll-back (Hawkins et al., 1990; Yan et al., 2016). Lack of coeval adakites, boninites, and HT/LP metamorphic rocks in the NAOB clearly contradicts the mid-ocean ridge subduction model (Kusky et al., 2003). Furthermore, no evidence supports the occurrence of early Cambrian collision in the NAOB. Instead, the subduction most likely lasted until ~460 Ma in this area (Han et al., 2012; Ye et al., 2018). Thus, the slab break-off model cannot satisfactorily describe the origin of the Baijianshan high-Mg diorites. The Dawan high-Mg andesites/diorites are regarded as the consequence of the slab roll-back, which formed at ~490 Ma (Meng et al., 2017; Ye et al., 2018). Thus, the much older (~535 Ma) Baijianshan diorites are unlikely applicable this model.

We propose that the Baijianshan high-Mg diorites were formed by partial melting of subducted sediments at the early stage, possibly the initial stage of oceanic subduction. Firstly, the  $\epsilon_{\text{Nd}}(t)$  and  $\epsilon_{\text{Hf}}(t)$  values of the granitoids derived gradually from enrichment to depletion from early to late (Fig. 8a, b), suggesting continuous increasing of mantle-

derived material (or/and juvenile crust input) during subduction (e.g. Liu et al., 2017). Secondly, The age of ~535 Ma is earlier than previous reported subduction-related rocks (520–460 Ma) (Han et al., 2012; Liu et al., 2016b; Meng et al., 2017; Wu et al., 2009; Ye et al., 2018; Zheng et al., 2019) ophiolites (480–520 Ma) (Gai et al., 2015; Yang et al., 2008) and high-pressure and low-temperature (HP/LT) metamorphic rocks (490–510 Ma) (Zhang et al., 2010) in the NAOB. Therefore, we suggest that the subduction in the NAOB began at ~535 Ma.

## 6.2. Petrogenesis of the Dawanbei and Dabanxi rhyolites

Based on the nature of their protolith and the pressure and temperature of melting, silicic igneous rocks are generally subdivided into A-, I-, S-, and M-types (Bonin, 2007). Several geochemical approaches have been made to discriminate between A-type granites and others (Eby, 1992; Whalen et al., 1987), including high Na<sub>2</sub>O + K<sub>2</sub>O contents and Ga/Al and molar Fe/Mg ratios, low CaO content, enriched in HFSE, and depleted in Sr and Eu (Bonin, 2007; Whalen et al., 1987). On a 10000 × Ga/Al versus Zr diagram, the Dawanbei and Dabanxi rhyolites plot in the field of A-type granites (Fig. 13a; Whalen et al., 1987). Although highly fractionated granites can yield high FeO<sup>T</sup>/MgO ratios, the Dawanbei and Dabanxi rhyolites plot within the A-type field on the (Zr + Nb + Ce + Y) versus FeO<sup>T</sup>/MgO diagram, which is generally used to distinguish A-type from highly differentiated granites (Fig. 13b). On the Yb + Nb versus Rb diagram of Pearce, 1996, these rhyolites plot in the WPG field (Fig. 13c) are classified as A<sub>2</sub> subtype according to the classification of Eby (1992) (Fig. 13d). The calculated zircon saturation temperatures of the Dawanbei and Dabanxi rhyolites are 779 °C to 829 °C (Table 1; weighted mean = 803 °C). Therefore, the A-type signature of the Dawanbei and Dabanxi rhyolites was further supported by relatively high temperature.

The Dawanbei and Dabanxi rhyolites most have low K<sub>2</sub>O (0.95–2.79 wt.%) contents with K<sub>2</sub>O/Na<sub>2</sub>O ratios of 0.16–0.66 (Table 1). Such low-K silicic rocks (e.g. trondhjemite and tonalite) could be formed either through fractional crystallization of basaltic magmas or through partial melting of basaltic rocks in the crust (e.g. Atherton and Petford, 1993; Rapp and Watson, 1995; Thy et al., 1990). We rule out fractional crystallization of mafic magma base on the following evidence: (1) the whole-rock  $\epsilon_{\text{Nd}}(t)$  values and trace-element ratios (e.g. U/Zr, Nb/Zr, and Th/Zr) of the Dawanbei and Dabanxi rhyolites are remarkably different from those of contemporaneous basalts and mafic intrusions (Fig. 10a), (2) there exists a clear compositional gap between the basalts and the rhyolites (Fig. 8), and (3) the volume of the rhyolites is far greater than that of the basalts (Fig. 3).

We favor an alternative explanation for the formation of the Dawanbei and Dabanxi rhyolites: the partial melting of mafic rocks. Many melting experiments conducted on mafic rocks at pressures of 1–38 kbar indicate pressure plays a key role in controlling melt composition (Beard, 1995; Beard and Lofgren, 1991; Qian and Hermann, 2013; Rapp et al., 1999; Rapp and Watson, 1995; Thy et al., 1990). Partial melting of basaltic rocks generally produces adakitic magmas at 10–38 kbar (Qian and Hermann, 2013; Rapp et al., 1999; Rapp and Watson, 1995; Sen and Dunn, 1994) and high-K silicic melts resembling calc-alkaline I-type granites at 7–8 kbar (Rapp and Watson, 1995; Sisson et al., 2005). Dehydration melting of basaltic rocks at shallow crustal levels (1–3 kbar) yields metaluminous to mildly peraluminous granodioritic to trondhjemitic melts (Beard and Lofgren, 1991; Thy et al., 1990). We attribute the high SiO<sub>2</sub> and Na<sub>2</sub>O, and low K<sub>2</sub>O contents of the Dawanbei and Dabanxi rhyolites to low-degree partial melting of a basaltic source, suggesting the melting temperature was ~900 °C, based on experimental results (Beard and Lofgren, 1991). Thus, the Dawanbei and Dabanxi rhyolites were likely generated by shallow (1–3 kbar) dehydration melting of basaltic rocks at ~900 °C. Reaching this melting temperature at such shallow depths requires external heat input; therefore, these A-type rhyolites were likely generated in an extensional environment,

**Fig. 14.** A schematic diagram to illustrate the tectonic evolution of the NAOB (see details in text). Abbreviations: TM-Tianshuihai-Mazar terrane, CA-Central Altyn, GI-great India, LA-Lhasa terrane, Q-Qaidam, SC-South China, NC-North China, MG-Mongolia, IC-Indochina.

where the crust tends to be thin and magmatic advection of heat can reach shallow crustal levels.

The Dawanbei and Dabanxi rhyolites have pronounced negative Sr, Eu, and Ti anomalies (Fig. 9c-f). According to experimental studies, the residuum left after dehydration melting of mafic rocks is plagioclase-rich (~50%), with apatite, ilmenite, and magnetite (Beard and Lofgren, 1991; Thy et al., 1990); therefore, we suggest that the significant negative Sr, Eu, and Ti anomalies in the Dawanbei and Dabanxi rhyolites are related to residual plagioclase and Ti-Fe oxides, respectively.

It is generally accepted that A-type granitoids are genetically related to non-compressional regimes such as rifting or extensional environment (Eby, 1992; Whalen et al., 1987). Based on the geochemical subdivision of A-type granites by Eby (1992), the Dawanbei and Dabanxi rhyolites belong to A<sub>2</sub>-subtype rocks (Fig. 13d). Their Y/Nb (2.22-3.63) and Yb/Ta (2.66-4.99) ratios are similar to those of IAB (Table 1). Furthermore, basalts from the bimodal volcanic sequence have high Zr (77.6-267 ppm), Nb (5.12-12.2 ppm), and Y (26.8-63.5 ppm) contents and Ti/Y (213-301), Gd/Yb (1.63-2.26) ratios, and low Hf/Ta (6.0-9.1)

ratios (Hao et al., 2013), distinguishes those rocks from MORB, OIB and IAT, but resembles back-arc basin basalts (BABB) in the Okinawa Trough. The occurrence of a back-arc basin is compatible with the sedimentary features of the upper member of Lapeiquan Formation (Fig. 3). Thus, the bimodal volcanic rocks emplaced during syn-rifting stage and the marine clastic sequence deposited during post-rifting stage, resembles the evolution history of the Okinawa Trough (Sibuet et al., 1987). Thus, the Dawanbei and Dabanxi A-type rhyolites were likely formed in a continental back-arc setting.

### 6.3. Tectonic implications

The assembly of Gondwana was completed with the closure of the Mozambique Ocean (650–530 Ma) and the associated amalgamation of East and West Gondwana during the Pan-African Orogeny (Li et al., 2018a), which led to the final docking of Antarctica, Australia, and Southern Africa with previously amalgamated India and East Africa along the Kuunga (Pinjarra) Orogen (Collins and Pisarevsky, 2005;

Meert, 2003). From late Neoproterozoic to early Cambrian, Gondwana was split into several continental blocks primarily by the Proto-Tethys and Iapetus oceans; the former separated Gondwana from the North China, South China, Tarim blocks, and several microcontinental blocks (e.g. Qaidam, Alax, Dunhuang, and etc) and the latter separated Gondwana from Laurentia and Baltica. Recent studies of East Asia have indicated that the Tarim, Dunhuang, Alax and North China blocks were located north of the Proto-Tethys Ocean, while numerous scattered continental and micro-continental blocks were found south of the Proto-Tethys Ocean (including the South China, Indochina, Tianshuihai-Mazar, Central Qilian, North Qinling, Oulongbuluke, and Qaidam blocks; e.g., Li et al., 2018a).

The Precambrian central Altun terrane lies in south of the NAOB and shares most features of the Precambrian basement and Mesoproterozoic to Neoproterozoic magmatic activity to those of the Yangtze Block (Song et al., 2012; Yu et al., 2013). Moreover, the detrital zircon U-Pb age spectra of the Altun Group and tectonic events were comparable with those of the Yangtze Block (Peng et al., 2019; Yu et al., 2013). Thus, the Central Altun terrane, as well as Central Qilian, North Qinling, Tianshuihai and Mazar, was microcontinental fragment that originated from the Yangtze Block at the late Neoproterozoic (Li et al., 2018a; Zhang et al., 2018). These terranes are most similar to the East Gondwana in the early Paleozoic, indicating that their history was closely related to the evolution of the Proto-Tethys Ocean.

The U-Pb age peaks of zircon in magmatic rocks of the NAOB are closest to those in the North Qilian, West Kunlun and North Qinling Orogenic Belt (Fig. 7), indicating that these tectonic domains experienced an almost identical evolution. The ~530 Ma fore-arc gabbros and monzogranites in the West Kunlun Orogenic Belt (Yin et al., 2020; Zhang et al., 2018), the ~520 Ma peraluminous granites and tholeiitic boninites in the North Qilian Orogenic Belt (Chen et al., 2014; Xia et al., 2012), and the 524 Ma boninites and boninite-like diabases along the Shangdan suture zone in the North Qinling Orogenic Belt (Li et al., 2015) suggest that subduction of the Proto-Tethys Ocean commenced at ~520–530 Ma. The ~535 Ma Baijianshan high-Mg diorites from this study are the earliest known subduction-related magmatic rocks and most likely mark the beginning of subduction of the Proto-Tethys Ocean lithosphere in the northern Altun Mountains. In specific, the initial subduction generally induces fore-arc extension and asthenospheric upwelling (Hall et al., 2003; Stern et al., 2012) which led to the partial melting of the subducted sediments; such sediment-derived melts would ascent and then interact with the mantle peridotites to generate the Baijianshan high-Mg diorites (Fig. 14a).

Once subduction starts, it generally progresses from low to high angles. Such a transition was common along the Circum-Pacific and Proto-Tethys tectonic belt, and led to slab rollback and trench retreat, which in turn result in back-arc extension. This process has been documented in the North Qilian from 490 to 445 Ma (Song et al., 2013), North Qinling from 514 to 460 Ma (Dong et al., 2011; Liu et al., 2016a), and West Kunlun Orogenic Belt during the early Cambrian (Yin et al., 2020).

The Dawanbei and Dabanxi A-type rhyolites, as a part of the bimodal volcanic sequence of the Lapeiquan Formation, were formed in a continental back-arc setting. Slab rollback and back-arc extension can explain the geochemical characteristics of the late Cambrian magmatism in the NAOB, including the coeval formation of the adakitic rocks (Meng et al., 2017) and high-Mg andesites and diorites (Meng et al., 2017; Ye et al., 2018). Slab rollback generally triggers asthenospheric upwelling to compensate for mantle wedge mass loss and progressively thins the crust and lithospheric mantle. Asthenospheric upwelling provides heat for melting the continental crust, subducted slab, and overlying sediments, generating granitic magmas (e.g., A- and I-type granitoids), adakitic rocks, and high-Mg andesites, respectively (Fig. 14b).

The mafic rocks and granitic rocks demonstrated that the subduction of the Proto-Tethys Ocean continued until ~460 Ma in NAOB (Han et al., 2012; Ye et al., 2018). The occurrence of S-type granites and low-Mg

adakitic rocks at ~440 Ma implied that the continental collision and thickening occurred at ~440 Ma (Wu et al., 2009; Yu et al., 2018), leading to the closure of the Proto-Tethys Ocean along the northern Altun Mountains. This process was related to the assemblage of the terranes in the eastern Asia (including Tianshuihai-Mazar, North Qinling, Central Qilian, Qaidam, Yangtze, Indochina, Sibumasu, etc) to the northern margin of Gondwana at ~440–430 Ma (Fig. 14c; Li et al., 2018a; Zhang et al., 2018). This amalgamation event was accompanied by formation of HP-UHP metamorphic belts (Song et al., 2014, 2018; Yang et al., 2018) and deposition of Early Devonian molasses on the abovementioned terranes (Li et al., 2018a).

## 7. Conclusions

- (1). The Baijianshan high-Mg diorites were emplaced at ~535 Ma. Their petrography, whole-rock geochemistry, and Nd-Hf isotopic compositions suggest that they were formed by interaction between subducted sediment-derived melts and mantle wedge peridotites.
- (2). The close spatial and temporal relationships and similar geochemistry for the Dawanbei and Dabanxi rhyolites suggest that they were derived from shallow (1–3 kbar) dehydration melting of basaltic rocks in a continental back-arc environment.
- (3). The Baijianshan high-Mg diorites indicate that the subduction of the Proto-Tethys Ocean in the northern Altun Mountains began at ~535 Ma. Slab roll-back triggered asthenospheric upwelling and induced back-arc extension, leading to the formation of A-type rhyolites and deposition of clastic marine sequence from ~520 to 480 Ma, and may have produced the trench-arc-back-arc system. Subduction most likely continued until ~460 Ma and the Proto-Tethys Ocean finally closed at ~440 Ma along the northern Altun Mountains.

## Declaration of Competing Interest

None.

## Acknowledgements

We are grateful to Professors Xian-Hua Li and Shuguang Song, and an anonymous reviewer for their insightful and critical comments which significantly improved the quality of this paper. This work is funded by the Fundamental Research Funds for the Central Universities (B200202137), the Laboratory for Marine Geology, Qingdao National Laboratory for Marine Science and Technology (MGQNLN-KF201817), the Natural Science Foundation of Jiangsu Province of China (BK20170873), the National Science Foundation of China (41702197), and the Natural Science Foundation of Shandong Province of China (ZR2018BD012). We appreciate the help of Mr. Kang Ni with field work, Dr. Jian Zhang and Dr. Jian-Zhen Geng with zircon U-Pb age dating and Hf isotope analyses, Professor Liang Qi and Ms. Jing Hu for elemental and Nd isotope analyses.
